Abstract

Based on density functional theory calculations we present a study of the gaseous oxidation of SO_2 to SO_3 by an anionic $\text{O}_3^-(\text{H}_2\text{O})_n$ cluster, $n = 0-5$. The configurations of the most relevant reactants, transition states, and products are discussed and compared to previous findings. Two different classes of transition states have been identified. One class is characterized by strong networks of hydrogen bonds, very similar to the reactant complexes. The other class is characterized by loose structures of hydration water and is stabilized by high entropy. At temperatures relevant for atmospheric chemistry, the most energetically favorable class of transition states vary with the number of water molecules attached. A kinetic model is utilized, taking into account the most likely outcomes of the initial $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$ collision complexes. This model shows that the reaction takes place at collision rates regardless of the number of water molecules involved. A lifetime analysis of the collision complexes supports this conclusion. Hereafter, the thermodynamics of water and O_2 condensation and evaporation from the product $\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_n$ cluster is considered and the final products are predicted to be O_2SO_3^- and $\text{O}_2\text{SO}_3^-(\text{H}_2\text{O})_1$. The low degree of hydration is rationalized through a charge analysis of the relevant complexes. Finally, the thermodynamics of a few relevant reactions of the O_2SO_3^- and $\text{O}_2\text{SO}_3^-(\text{H}_2\text{O})_1$ complexes are considered.

1 Introduction

One of the most debated subjects within atmospheric chemistry is the mechanisms leading to cloud formation. This is due to the combination of lacking success in constructing predictive models and the high impact of clouds on a variety of atmospheric phenomena (Solomon et al., 2007). Most noticeable is the understanding and forecasting of weather and climate (Simpson and Wiggert, 2009; Rosenfeld, 2006; Spracklen et al., 2008; Carslaw et al., 2002; Marsh and Svensmark, 2000).

Interactive Discussion

A known prerequisite for formation of a cloud droplet is a cloud condensation nucleus (CCN) onto which water vapour may condense. The chemistry and physics behind CCN formation is, however highly complex and may involve both solid and liquid particles (Zhang et al., 2007; Pierce and Adams, 2006; Falsig et al., 2006; Nadykto et al., 2008; Gross et al., 2008; Madsen et al., 2008, 2011) and may be based mainly on organic or inorganic species or a mixture of both (De Gouw and Jimenez, 2009; Kanakidou et al., 2005; Kirkby et al., 2011). One of the most important species involved in CCN formation is sulphuric acid, mainly due to its high water affinity (Liss and Lovelock, 2007; Charlson et al., 1987). The predominant source of atmospheric sulphuric acid is the well known UV light induced oxidation of SO₂. Although consisting of several elementary reactions the actual sulphur oxidation step,

is believed to be rate limiting (Seinfeld and Pandis, 1998; Wine et al., 1984).

Clearly complementary to this mechanism, a number of experimental and field based studies have found correlations between cosmic rays intensities and various cloud or aerosol parameters (Kirkby et al., 2011; Svensmark et al., 2009; Enghoff and Svensmark, 2008; Harrison and Carslaw, 2003). Cosmic rays are the primary source of atmospheric ionization and currently, ions are the most likely candidate responsible for these correlations. Although other micro- and macrophysical mechanisms may be important as well, interest have gathered around alternative mechanisms for H₂SO₄ formation involving the presence of one or more ions (Yu et al., 2008). However, the chemical and physical interactions involved in such a mechanism are still largely unresolved. The lack of knowledge of these fundamental processes is a major constraint towards the final assessment of the importance of ion induced cloud formation (Solomon et al., 2007).

Upon entrance of a cosmic ray into the atmosphere, a cascade of free electrons and various cations are produced. Although both cations and anions may be of interest for atmospheric nucleation, recently, more interest have gathered around the role of the anions and hence the fate of the electrons (Nadykto et al., 2006; Kurtén et al., 2009).

Interactive Discussion

A free electron is thermally unstable and will most likely, rapidly attach to an O₃ molecule with a significant energy gain. The O₃⁻ anion has a high water affinity and will, dependent on humidity and temperature, attract a number of H₂O molecules creating a small molecular cluster. Our previous studies show that at least 5 hydration water molecules will be present at usual atmospheric conditions (Bork et al., 2011b). Any subsequent chemistry involving the O₃⁻(H₂O)_n clusters will thus, at least initially, involve 5 water molecules.

The reactivity of O₃⁻(H₂O)_n has previously been evaluated with respect to a few chemical species including CO₂, CH₃CN, N₂O₅, and DNO₃ (Fehsenfeld and Ferguson, 1974; Yang et al., 1991; Wincel et al., 1995, 1996). Of particular interest for sulphuric acid formation is the reaction

which has been investigated by Fehsenfeld and Ferguson (1974). The observed rate constant was determined to $1.7 \times 10^{-9} \text{ cm s}^{-1}$. However, to the best of our knowledge, no studies of Reaction (R2) has included the effect of hydration. Given our findings concerning the high water affinity of O₃⁻, this should be performed for obtaining data relevant for atmospheric chemistry.

We have performed a density functional theory investigation of the reactivity of O₃⁻(H₂O)_n with SO₂, $n = 0-5$. Our main objective was to determine the reaction rate of SO₂ oxidation via this mechanism. However, a number of other possible chemical outcomes have been considered as well. These include re-evaporation of SO₂, evaporation of O₃ and O₂ and equilibrium with water. The main reactions are illustrated in Fig. 1.

Initially, the structures of all reactants, transition states, and products are thoroughly investigated and the thermodynamics considered. Hereafter, a simple kinetic model is set up to determine the reaction rates. The distribution of the final products is described and rationalized using molecular charges. Finally, a few relevant reactions of the end products are considered.

2 Computational details

All electronic structure calculations have been performed using the Gaussian 09 package (<http://gaussian.com/>) and all computational parameters are thoroughly described in a previous paper (Bork et al., 2011b). Here, a brief overview follows.

5 Ab initio calculations on radical systems, anionic systems, and hydrogen bonded networks require special attention with respect to several parameters in order to ensure reliable results. The extra electrons of anions are known to occupy diffuse, long ranging orbitals and hence require similar basis sets (Jensen, 2010). Also, the most common density functional theory (DFT) functionals have problems in this regard (Yanai et al.,
10 2004).

To address these issues we have utilized the CAM-B3LYP DFT functional (Yanai et al., 2004) and the aug-cc-pVDZ basis set (Dunning, 1989). The CAM-B3LYP functional is a modification to the well known B3LYP functional, including increasing Hartree-Fock exchange at increasing distances. We have previously demonstrated excellent agree-
15 ment between CAM-B3LYP/aug-cc-pVDZ and benchmark UCCSD(T)-F12/VDZ-F12 calculations (Bork et al., 2011b). Of further interest with respect to this study, it has been shown that CAM-B3LYP is superior to B3LYP with respect to evaluating classical activation barriers (Peach et al., 2006; Yanai et al., 2004).

The presence of multiple water molecules require a thorough sampling of configu-
20 rational space. For structure optimizations we have utilized the simulated annealing technique which is able, not only to determine the nearest local minima, but also to migrate from minima to minima. Thereby, each calculation scans a large number of different configurations and hence, provide a much better sampling of configurational space (Corana et al., 1987).

Interactive Discussion

Transition states were found using the Synchronous Transit and Quasi-Newton methods (STQN) (Peng et al., 1996) as implemented via the QST keyword. The initial guess for the transition states were obtained partly via structural analyses of the reactants and products and partly via scans of configurational space.

5 For analyzing the charge distribution of the various clusters, we have utilized the Bader charge partitioning method (Bader, 1998, 1990). The method is based on partitioning the electronic density by zero-flux surfaces and has a much better theoretical basis than most other charge partitioning methods. Previously, this method has successfully been used to describe both charged systems (Bork et al., 2011a) and water
10 containing systems (Henkelman et al., 2006).

3 Results and discussion

3.1 Structures and thermodynamics

Initially, all $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$, $\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_n$, and $\text{SO}_3^-(\text{H}_2\text{O})_n$ structures ($n = 0-5$) were thoroughly scanned using simulated annealing at the Hartree-Fock (HF) level. The
15 5–15 most stable structures were then re-optimized using DFT. In no cases were significant structural discrepancies between the most stable structures at the HF and DFT levels found.

The ground state structures of the initial collision complexes are shown in Fig. 2. In all cases, the O_3 and SO_2 molecules are found in configurations with one of the O_3 oxygen atoms clearly coordinated to the sulfur atom. The bond length is quite short, between 1.92 and 1.97 Å, indicating a relatively strong bond between the molecules. The SO_2 and O_3 molecules are thus positioned such that transferring an oxygen atom may occur without further structural rearrangement.

25 In the $n = 0$ and $n = 1$ cases, the remaining atoms of the O_3 molecule are turned away from the SO_2 molecule. As one more water is added, the O_3 arranges as to maximize the number of hydrogen bonds and hence, a more dense configuration is obtained.

Interactive Discussion

Adding the 3rd, 4th and 5th water, the only noticeable difference is the coordination of the water molecules being structured in 3 and 4 membered rings.

We note that many structures are almost iso-energetic, both at 0 Kelvin and at standard conditions. Hence, we conclude that the structures are resembling a liquid phase and that many other structures than the ones presented in Fig. 2 are found at atmospheric conditions.

Based on our previous studies, the thermodynamics of forming the collision complex, corresponding to

were hereafter readily available (Bork et al., 2011b). The potential energy surfaces are shown in Fig. 3.

All binding energies are large and positive and the $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$ collision complexes are thus likely to form at atmospheric conditions. As expected, the binding energy of the SO_2 molecule is largest for small values of n . This is a consequence of the effect of the water molecules in dispersing and stabilizing the charge of the O_3^- ion. This stabilization reduces the energy gain of any further clustering.

Following the outline in Fig. 1, the oxygen transfer reaction was investigated,

Due to the $\text{O}_2\text{-O-SO}_2$ configuration of the reactant structures, a series of transition states were readily found and are illustrated in Fig. 4.

Minor structural differences are found, depending on the level of hydration. For $n = 0-2$, the O_3 molecule is turned away from the SO_2 molecule, which yields a minimum S-O distance close to 1.71 Å. For $n = 3-5$, the O_3 molecule is positioned similar to the ground state structures, inducing longer S-O distances of ca. 1.80 Å. A similar trend in the O-O bond distance is found, here referring to the bond being broken during the reaction. These are found to be around 1.69 Å and 1.75 Å for $n = 0-2$ and $n = 3-5$, respectively. In all cases, the water molecules are tightly structured and hence, this class of transition states is denoted “tight”.

Interactive Discussion

Although some configurational differences are found at varying degree of hydration these are not reflected in the corresponding energy barriers, shown in Fig. 5. The free energy activation barrier for the water free system is found to 27.6 kJ mol^{-1} and is, as expected, decreased by adding the first and second water molecule. However, the addition of more water molecules tend to increase the energy barrier, i.e. stabilize the reactant complexes more than the transition states. This is somewhat surprising since many studies have found an increasing catalytic effect as more water is present (Larson et al., 2000; Niedner-Schatteburg and Bondybey, 2000). However, in this case the lowest barrier is found for the systems containing exactly 2 water molecules. We note that this is regardless of considering ΔH or ΔG within the temperature region of interest. At standard conditions, the free energy barrier is in the $n = 2$ case reduced to just 16.6 kJ mol^{-1} which is a reduction of 11 kJ mol^{-1} compared to the dehydrated structure.

While scanning configurational space, a second class of transition states was found. Within this class, the transition states are characterized by a much looser structure of hydrogen bonds even though the configurations of the actual reactants (the $\text{O}_2\text{S-O-O}_2$ complex) are very similar. These are shown in Fig. 6 and are denoted “loose” due to the loose structure of the water molecules.

Despite a much less ordered structure, the actual reactant complexes ($\text{O}_2\text{-O-SO}_2$) are more similar at varying degrees of hydration than within the “tight” class of transition states. In the “loose” transition states, S-O distances of ca. 1.71 \AA , and a O-O distances of ca. 1.69 \AA are found regardless of the number of water molecules. These distances are almost identical to the ones found in the “tight” transition states for $n = 0-2$ and may thus be interpreted as the optimal transition state configuration at low degree of water interaction.

Examining the energy barriers of the “loose” transition states, as expected we find the ΔH barriers significantly increased. Obviously, this occurs since the stabilization of the hydrogen bonded network of water molecules is lost. This is especially pronounced for $n \geq 3$, since the $n = 3$ cluster is the smallest structure capable of forming a ring of

Interactive Discussion

water molecules.

However, considering also entropy at standard conditions we see that the “loose” transition states are in fact more favored for $n = 3$ and 4. The differences are about 8 and 5 kJ mol⁻¹ for $n = 3$ and 4, respectively and these “loose” transition states are thus significantly favored at standard conditions. Further, at $n = 5$ the values of ΔG are practically identical.

The energy barrier for the corresponding, electrically neutral reaction has been evaluated both theoretically and experimentally, albeit not including the effect of water. Using B3LYP and a triple zeta basis set, Jiang et al. (2009) determined the barrier to be around 83 kJ mol⁻¹, while Sander et al. (2006), based on time-of-flight mass spectrometry by Davis et al. (1974), suggest an activation barrier of at least 58 kJ mol⁻¹. Hence, we conclude that although the reaction may be catalysed by the presence of a few water molecules, the extra electron itself will dramatically enhance the oxidation reaction.

The structures of the product complexes were investigated as well and are shown in Fig. 7. In all cases, the same configuration of the SO₃ and O₂ molecules were found, forming an O₃S-O₂ complex. The S-O distances are between 1.81 and 1.85 Å and given the stability of the HSO₄⁻ ion, these configurations may be of relevance for the further outcome of these complexes. At 0 Kelvin, all the most stable structures display a strong network of hydrogen bonds while other, less ordered structures become relevant at elevated temperatures. As expected, we find Reaction (R4) highly exothermic at values between 135 and 175 kJ mol⁻¹. It is thus clear that the reverse reaction will be without relevance.

Another theoretically possible outcome of the initial collision complex is evaporation of O₃, leaving a SO₂⁻(H₂O)_{*n*} cluster behind. Although not performing a full simulated annealing configurational analysis of the clusters, we conclude that this reaction is at least 130 kJ mol⁻¹ endothermic and hence without relevance under atmospheric conditions.

Interactive Discussion

Besides discarding the relevance of O₃ evaporation from the O₃⁻SO₂(H₂O)_n cluster, these calculations can be used for an evaluation of the accuracy of the calculational methods. Considering the *n* = 0 systems, i.e. the reaction

5 we find that this is 92.1 kJ mol⁻¹ endothermic. We also note that this energy equals the difference between the electronegativities of O₃ and SO₂, given as 96 kJ mol⁻¹ (Lide, 1997). This very good agreement between theoretical and experimental values is a strong argument in favor of the quality of the present results.

10 Finally, the structures of the SO₃⁻(H₂O)_n clusters were examined since evaporation of O₂ is an obvious possibility,

The structures were similar to the product clusters shown in Fig. 7 just without the O₂ species, and have all maintained a strong hydrogen bonded network. The structures are shown in the Supplement.

15 The thermodynamics of O₂ evaporation were hereby available and it is thus clear that the bond between SO₃⁻ and O₂ is quite weak for *n* ≥ 2, but quite strong for *n* ≤ 1. Considering the large release of internal energy due to the oxidation, the O₂ molecule will have a high probability of evaporating, but given the large concentration of atmospheric O₂ the equilibrium will quickly settle. See also Sect. 3.4.

20 Finally, the thermodynamics of the entire reaction chain, as illustrated in Fig. 1, are available,

Hereby, we are able to make a second assessment of the quality of the results by considering the *n* = 0 reaction as the sum of the reactions

Interactive Discussion

Hereby, can compare our value of -217 kJ mol^{-1} to the experimental ΔG° of -196 kJ mol^{-1} (Lide, 1997). Considering the inherent difficulties within DFT of describing charge transfer reactions and the potential multireference problems of O_2 and O_3 , the agreement is very satisfactory.

3.2 Kinetics

The main objective of this study is to examine the kinetics of SO_2 oxidation to SO_3 by an $\text{O}_3^-(\text{H}_2\text{O})_n$ cluster. Having established the thermodynamic properties of the reactants, products and transition states we proceed to this point.

To determine the total rate of oxidation, steady state for the pre-reactive complex, $\text{O}_3^-\text{SO}_2(\text{H}_2\text{O})_n$, is assumed. Hereby we obtain the following set of reactions

$$\frac{\partial [\text{O}_3^-\text{SO}_2(\text{H}_2\text{O})_n]}{\partial t} = 0 \quad (1)$$

$$= Z_{\text{coll}} - r_{\text{ox}} - r_{\text{SO}_2 \text{ evap}} \quad (2)$$

where r_{ox} and $r_{\text{SO}_2 \text{ evap}}$ are the reaction rates of the oxidation and SO_2 evaporation processes, respectively. Z_{coll} is the rate of collisions leading to formation of the collision complex. Recall that evaporation of O_3 is highly endothermic and may be disregarded. At this point we consider only fixed values of n , since it later can be concluded that varying hydration will not alter the kinetics. See Sects. 3.3 and 3.4 for further analysis.

Since both r_{ox} and $r_{\text{SO}_2 \text{ evap}}$ must depend linearly on the concentration of $\text{O}_3^-\text{SO}_2(\text{H}_2\text{O})_n$ we obtain

$$Z_{\text{coll}} - [\text{O}_3^-\text{SO}_2(\text{H}_2\text{O})_n](k_{\text{ox}} + k_{\text{SO}_2 \text{ evap}}) = 0, \quad (3)$$

where “ k ” denote the corresponding rate constants.

Printer-friendly Version

Interactive Discussion

Further, since the oxidation is highly exothermic no backwards reaction is possible and hence, the total reaction rate can be obtained as

$$r_{\text{tot}} = r_{\text{ox}} \quad (4)$$

$$= k_{\text{ox}} [\text{O}_3^- \text{SO}_2(\text{H}_2\text{O})_n] \quad (5)$$

$$= Z_{\text{coll}} \left(1 + \frac{k_{\text{SO}_2 \text{ evap}}}{k_{\text{ox}}} \right)^{-1} \quad (6)$$

where the final equation is obtained by inserting the expression for $[\text{O}_3^- \text{SO}_2(\text{H}_2\text{O})_n]$ from Eq. (3). Further assuming that both oxidation and SO_2 evaporation can be described by Arrhenius equations we obtain

$$\frac{r_{\text{tot}}}{Z_{\text{coll}}} = \left(1 + \frac{A_{\text{SO}_2 \text{ evap}}}{A_{\text{ox}}} \exp \left(- \frac{\Delta E_{\text{SO}_2 \text{ evap}} - \Delta E_{\text{ox}}}{RT} \right) \right)^{-1} \quad (7)$$

where the ratio $r_{\text{tot}}/Z_{\text{coll}}$ denote the fraction of $\text{O}_3^- \text{SO}_2(\text{H}_2\text{O})$ complexes, in which SO_2 is oxidized.

The differences in activation energies, $\Delta E_{\text{SO}_2 \text{ evap}} - \Delta E_{\text{ox}}$, are directly obtained from Fig. 3. The prefactors were obtained using transition state theory in the harmonic approximation (Hänggi et al., 1990; Billing and Mikkelsen, 1996). The prefactor of oxidation is then given as

$$A_{\text{ox}} = \frac{\prod \nu_{\text{reac}}}{\prod \nu_{\text{TS}}^\dagger} \quad (8)$$

where “ ν ” denote the vibrational frequencies of the reactants and transition states. The \dagger symbol indicate that the imaginary frequency should be omitted.

We here note that the reactant configuration, should be the first stable configuration into which the transition state falls upon relaxation and not necessarily the absolute ground state. In the class of “tight” transition states, the configuration actually relaxes

N. Bork et al.

Interactive Discussion

into the ground state, but in the class of “loose” transition states this is not the case. These relax into a configuration, not much different from the transition state itself.

Since evaporation of SO₂ is barrierless, there were no transition states in which to evaluate the frequencies. In stead, we loosely estimated these by gradually moving the SO₂ away from the cluster and continuously evaluating the resulting frequencies. Although this method is rough, we emphasize that the accuracy is adequate for the present purpose, namely to evaluate the fraction of reactive collisions from Eq. (7). This was ensured by a sensitivity analysis showing no major discrepancies, even considering an error of two orders of magnitude. All relevant frequencies are given in the Supplement.

Finally, we evaluate the fraction of reactive collisions at standard conditions. Regardless of the number of water molecules we find that

$$\frac{r_{\text{tot}}}{Z_{\text{coll}}} > 0.995, \quad (9)$$

i.e. practically all collisions will lead to oxidation. The main reason is not a particularly small energy barrier but rather that any other chemical fate shown in Fig. 1 requires a significantly higher activation energy.

The rate of oxidation of SO₂ by an anionic O₃[−](H₂O)_n cluster may thus simply be estimated using classical collision theory,

$$Z_{\text{coll}} = N_{\text{SO}_2} N_{\text{cluster}} \pi d^2 \sqrt{\frac{8k_B T}{\mu \pi}} \quad (10)$$

where N is the number of species pr. unit volume, $d = d_{\text{SO}_2} + d_{\text{cluster}}$ is the total collision cross section, k_B is Boltzmann’s constant, and μ is the reduced mass (Atkins, 2001; Billing and Mikkelsen, 1996).

Comparison with experimental data is only possible for the dehydrated system where Fehsenfeld and Ferguson (1974) measured the rate constant to $1.7 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ at $T = 296 \text{ K}$. In this case, assuming $d = 5.5 \text{ \AA}$, we obtain a rate constant of $1.1 \times$

N. Bork et al.

Interactive Discussion

$10^{-10} \text{ cm}^3 \text{ s}^{-1}$. We consider it most likely that the order of magnitude difference reflects a net attractive potential between the O_3^- ion and SO_2 increasing the collision rates. Alternatively, inaccuracies in the original experimental measurements may be the reason. In any case, the results are in reasonable accordance and oxidation of SO_2 by an $\text{O}_3^-(\text{H}_2\text{O})_n$ cluster is undoubtedly fast and should be considered when studying ionic atmospheric chemistry.

3.3 Lifetime of $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$

Although there is no other likely fate of the isolated $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$ complex other than SO_2 oxidation, collision with other atmospheric species could induce other possible end products. This is dependent of the expected lifetime of the $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$ complex which was evaluated using hTST. The lifetime, τ , is thus given as

$$\tau = k_{\text{ox}}^{-1} = A_{\text{ox}}^{-1} \times \exp\left(\frac{\Delta E_{\text{ox}}}{RT}\right) \quad (11)$$

where A_{ox} is given in Eq. (8). Hereby, the lifetimes are evaluated to be in the picosecond regime, illustrated in Fig. 8. For comparison, the average times between collisions with N_2 , O_2 and H_2O (50% relative humidity) are illustrated as well.

From this it is apparent that the most reactive complexes, i.e. the $n = 2, 3$ and 4 complexes, typically reacts before colliding with any other species. The remaining complexes will experience a few N_2 collisions and perhaps a single collision with O_2 . Collision with any other species, including H_2O is rarely experienced.

We thus conclude that the most likely fate of the $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$ complex undoubtedly is SO_2 oxidation since any other outcome require a large extra activation energy and since the complex is too short lived to experience collision with another molecule which may induce pathways not considered here.

3.4 Equilibrium with H₂O and O₂

From the previous section, growth via stepwise water condensation on the SO₂O₃⁻(H₂O)_n cluster has been excluded due to kinetics, i.e. the cluster is too short lived for the equilibrium to settle. Even though some water molecules possibly may evaporate from the cluster prior to Reaction (R4), we note that this will not alter the overall kinetics, since the reaction will take place at collision rates regardless of the number of attached water molecules. In other words, once the collision complex is formed no other fate than Reaction (R4) is possible, regardless of the state of hydration. Consequently, the degree of hydration of the SO₂O₃⁻(H₂O)_n cluster is not of immediate interest.

After the reaction, both the SO₃⁻O₂(H₂O)_n and SO₃⁻(H₂O)_n clusters will, most likely, be stable enough to reach thermal equilibrium via H₂O and O₂ evaporation and condensation. The thermodynamics of these equilibria, i.e.

are therefore considered. All values are available from the previous calculations and are shown in Fig. 9.

Considering first the equilibrium with oxygen, i.e. Reaction (R11), we see that the oxygen binding energy to the dehydrated SO₃⁻ anion is quite strong, but also that it quickly and smoothly converges to a value of ca. -4 kJ mol⁻¹ as water is added. Considering the equilibrium with water, i.e. Reactions (R12) and (R13), we observe that the thermodynamics of water condensation is considerably weaker than expected and even weaker than the O₂ binding energies. Although binding energies are positive for the smallest clusters, the binding energy becomes negative for condensation of the 4th and 5th water molecule and hence, large clusters are destabilized.

Interactive Discussion

Experimental data is available for Reaction (R13) in the $n = 0$ case. Fehsenfeld and Ferguson (1974) determined this ΔG to be $-24.7 \text{ kJ mol}^{-1}$ in fairly good accordance with the ca. -17 kJ mol^{-1} found here.

A likely outcome of the reactants is thus as follows. Immediately after the reaction the clusters have a large amount of excess energy due to the thermodynamics. The cluster will most likely not be able to accommodate this energy and evaporation of O_2 and one or more H_2O will occur. The clusters considered here bind O_2 stronger than H_2O and further due to the higher concentration of O_2 , this equilibrium will settle first.

Via the law of mass action,

$$\frac{[\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_n]}{[\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_{n-1}]} = [\text{H}_2\text{O}] \times \exp\left(-\frac{\Delta G}{RT}\right) \quad (12)$$

it is realized that the main product is dehydrated. Assuming standard conditions and 50% relative humidity, this configuration constitutes ca. 80–90% of the resulting clusters, depending on altitude. The remaining 20–10% of the clusters are mainly found as $\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_1$ with any other constitution populating less than 1%.

3.5 Charge analysis

Comparing the results of the previous section to other modeling and theoretical studies, it is surprising that the most stable configuration is without water. Most other studies on both cations and anions have found a tendency to attract at least a few water molecules at standard conditions. The best explanation is found via a molecular charge analysis of the systems, shown in Fig. 10. Included for comparison is our previous results for the O_3^- based clusters.

From this, a clear correlation between the charge and the binding energy of the water is seen. If a large amount of charge is distributed to the water molecules, proportional reductions in the electrostatic energy are obtained yielding a stronger binding energy. This is fully in line with our previous findings (Bork et al., 2011b).

Interactive Discussion

It is also apparent that the size of the non-water part of the cluster is important. This is due to the extra electron being more delocalized in larger molecules, reducing the electrostatic stress on the system and hence reducing the need for further electronic delocalization through cluster growth.

5 Apparently, the O_2SO_3^- cluster is almost large enough to facilitate the extra electron by itself, since only about 0.03 e is being distributed to the first water molecule. Consequently, the binding energy is just ca. 8 kJ mol^{-1} which is below the critical energy of cluster growth. This corresponds to the value of ΔG where Eq. (12) equals 1, separating the regimes of cluster growth and evaporation.

10 3.6 Further chemistry of SO_3^-O_2

During charge neutral, photo induced, atmospheric H_2SO_4 synthesis, the rate determining step is oxidation of SO_2 to SO_3 , shown in Reaction (R1) (Seinfeld and Pandis, 1998; Wine et al., 1984). Hence, once the neutral SO_3 molecule is formed, the mechanism leading to H_2SO_4 is well known and the formation is relatively fast.

Originating from a SO_3^- based cluster, non-charged SO_3 may readily form by collision with O_3 . Considering their electronegativities, the charge transfer reaction

15 will be ca. 40 kJ mol^{-1} exothermic but should be studied further with respect to the effects of O_2 and H_2O (Lide, 1997). We note that formation of O_3^- will enable the oxidation process to repeat and hence, close a catalytic cycle. Exploring electronic induced catalysis in SO_3 and H_2SO_4 formation is of particular interest for explaining the observed correlations between cloud and aerosol parameters and cosmic ray influx
20 (Kirkby et al., 2011; Svensmark et al., 2009; Enghoff and Svensmark, 2008; Harrison and Carslaw, 2003).

However, the chemical fate of O_2SO_3^- may be different from neutral SO_3 and subsequently neutral H_2SO_4 . Here, we note that the species H_2SO_4^- is without atmospheric relevance since the HOMO orbital is very high in energy (NIST, 2011).

Interactive Discussion

The most obvious other outcome is synthesis of HSO_4^- via reaction with O_2 and H_2O ,
 $\text{SO}_3^- + \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{HSO}_4^- + \text{HO}_2$. (R15)

Even though this reaction is ternary and may have a significant energy barrier and complex dynamics, the necessary reactants are all abundant and therefore, this reaction is a likely candidate as well.

Naturally, HSO_4^- and H_2SO_4 are closely related and share many properties, but should Reaction (R15) occur, the catalytic effect of the electron will terminate due to the high stability of the HSO_4^- ion. The competing rates of Reactions (R14) and (R15) will thus ultimately determine how many SO_2 oxidations each free electron may induce.

4 Conclusions

The role of ion-induced H_2SO_4 formation has for a long time lacked a proper explanation of the chemical and physical mechanism. We have performed density functional theory calculations of one of the most important reactions in a proposed mechanism for ion induced SO_2 oxidation (Fig. 1).

Motivated by a previous study (Bork et al., 2011b), we find that $\text{O}_3^-(\text{H}_2\text{O})_n$ clusters are capable of further clustering with SO_2 , creating $\text{O}_3^-\text{SO}_2(\text{H}_2\text{O})_n$ clusters (Fig. 2). A variety of possible outcomes of these clusters have been examined. The most likely outcome, requiring the smallest activation energy, is oxidation of SO_2 to SO_3^- .

Two classes of transition states were identified. One characterized by a network of hydrogen bonds and one characterized by high entropy (Figs. 4 and 6). At standard conditions, both are important and will significantly contribute to the total reaction rate (Fig. 5).

Using a simple kinetic model, we determined that the reaction takes place at collision rates, in accordance with the available experimental data. Further, the lifetime of the collision complex were determined to exclude other possible outcomes, induced by collision with other reactants (Fig. 8).

Interactive Discussion

Assuming thermal equilibrium, we determined the composition of the resulting products by considering their equilibrium with H_2O and O_2 (Fig. 9). Using the law of mass action, the most likely products were determined to be SO_3^-O_2 and $\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_1$ (Fig. 7) at ca. 80–90% and 10–20% population, respectively, dependent on altitude.

Finally, these results were rationalized using molecular charge analysis showing a reduced tendency of charge delocalization for these clusters. In accordance with previous results, the degree of charge delocalization was proportional to the binding energies and the low degree of hydration could be explained (Fig. 10).

Fig. 2. Ground state structures of the initial collision complexes, $\text{SO}_2\text{O}_3^-(\text{H}_2\text{O})_n$, $n = 0-5$. For all water containing structures, a strong hydrogen bonded network is preferred. Hence, many 3 and 4 membered rings are formed. Sulfur (yellow), oxygen (red), hydrogen (white).

Fig. 3. Relative potential energy of the most important structures involved in the oxidation of SO₂ to SO₃ by an anionic O₃⁻(H₂O)_n cluster, $n = 0-5$. “W” is shorthand for water. The values are tabulized in the Supplement.

Fig. 4. Structures of the class of transition state complexes characterized by a strong network of hydrogen bonds. These are very similar to the reactant complexes, shown in Fig. 2, and are denoted “tight” due to the tight water structures. The water free structure is included for completeness. The dashed bonds indicate the bonds which are active in the reaction. Sulfur (yellow), oxygen (red), hydrogen (white).

Fig. 5. ΔH and ΔG of the two classes of transition states as function of number of water molecules, n , at standard conditions. The structures of the “tight” and “loose” transition states are shown in Figs. 4 and 6, respectively. The barrier of the charge neutral reaction is at least 58 kJ mol^{-1} for $n = 0$. The values are tabulized in the Supplement.

Fig. 6. Structures of the class of transition state complexes characterized by high entropy. These are denoted “loose” due to the loose water structures. The water free structure is included for completeness. The dashed bonds indicate the bonds which are active in the reaction. Sulfur (yellow), oxygen (red), hydrogen (white).

Fig. 7. Configuration of the product complexes $\text{SO}_3^-\text{O}_2(\text{H}_2\text{O})_n$. The O_2 species is coordinated to the sulfur atom with S-O distances between 1.81 and 1.85 Å. The high concentration of atmospheric O_2 ensures a high population of these complexes. See also Sect. 3.4.

Fig. 9. Gibbs free energies of growth of the clusters via H_2O and O_2 condensation. “W” is shorthand for water. The regimes of evaporation and condensation under standard conditions and 50 % relative humidity are illustrated, determined using Eq. (12). Assuming thermal equilibrium, the final products are mainly O_2SO_3^- and $\text{O}_2\text{SO}_3^-(\text{H}_2\text{O})_1$. The experimental data is from Fehsenfeld and Ferguson (1974).

N. Bork et al.

Fig. 10. Accumulated Bader charges on the water molecules (W_n) in SO_3^-O_2 , SO_3^- and O_3^- based clusters. This charge is proportional to the binding energies and the larger the non-water part of the cluster, the less charge on the water molecules and hence, the weaker the binding.
